UPDATED RESEARCH DOSSIER

AI Options Trading

Evidence, return targets, and a testable system

Updated evidence: checkpoint and larger PnL sample.
Twenty-one screenshots show a named model checkpoint and $53,917 of displayed realized profit. About 85% comes from one opening-date cohort. Daily account returns remain unverified.

Inside this report

- 21-image audit, cohort revisions, and profit concentration
- Checkpoint, training metrics, and model reconstruction
- Published research, data, labels, and execution design
- Risk budgets, rollout gates, and verification requests

Updated October 29, 2026 with both follow-up batches. No model was trained, no backtest was run, and no trade was placed. Proposed experiments and illustrative arithmetic are labeled throughout.

1. Decision and scope

An AI options research system is feasible to build. Across all 21 supplied screenshots, there is now stronger evidence of a checkpointed model workflow: a named model artifact, experiment runs, custom metrics, and a dashboard view explicitly labeled live. The larger August table displays $53,917 of realized profit across two broker columns. These are useful new observations, but neither the training curve nor the dollar table establishes daily returns on total account equity. [A8-A17]

The percentage formula visible in the original and follow-up images uses option entry cost, while each dated row groups positions opened on that date. These are trade-cohort results, potentially accumulated across several holding days. The displayed $53,917 August profit is also concentrated: $45,855, approximately 85.0%, comes from the August 26 opening cohort. Its constituents and holding periods are not shown. [A1, A13, A14, A17]

The first screenshot still has a separate percentage reconciliation issue. Under its stated formula, five row percentages imply roughly $130,730 of total entry cost. Its realized and unrealized figures imply $7,581 of net profit, or about 5.8% of that cost, while the total percentage reads 7.7%. The newer dollar table largely reconciles, but its cropped percentage and cost fields do not resolve the earlier calculation.

The productive objective is to discover whether a strategy has positive, repeatable account-level returns after executable trading costs, then estimate the risk and capacity that edge supports. Treat the 1% daily target as a hypothesis to test. The visible concentration makes the recurrence and survivability of large winners particularly important research questions.

Recommended starting point: liquid ETF options; a small, auditable universe; regularized linear and rule baselines; boosted trees and a small supervised neural model evaluated alongside one another; explicit option-return labels; realistic execution; and a separate risk controller. Compare gain-only prediction with an auxiliary tradability output as a proposed experiment. The screenshots do not establish that the owner uses this exact architecture or loss.

This revised report separates attachment observations, primary-source findings, explicitly labeled inferences, and proposed experiments. No source code, model weights, historical option dataset, or brokerage statement was supplied. No model was trained, no backtest was run, and no trade was placed in preparing either edition.

2. What the 21 screenshots reveal

The first seven images are A1-A7, the ten-image follow-up is A8-A17, and the four additional views are A18-A21. Several images repeat or horizontally reveal the same table or run, so 21 images do not constitute 21 independent performance observations.

Evidence	Direct observation	What it supports	What remains unknown
A1: wide PnL view	`txrdash`, `m14.fund3`, broker and option-side columns, realized/unrealized figures, entry-cost formula	Cohort accounting and broker attribution	NAV, costs, holding periods, percentage-total logic

Evidence	Direct observation	What it supports	What remains unknown
A2, A5, A7	August opening-date tables with Alpaca subtotals $34,932 and $11,973	Different snapshots of cohort outcomes	Calendar-day equity changes and complete open exposure
A3: Health	Scanning, features, selection, routing, exits, authentication, and ledger checks	A staged operational workflow	How each health condition is defined and enforced
A4: Positions Map	Calls labeled $23,773; several underlying names	A portfolio visualization	Exact structures, expiries, sizes, and net Greeks
A6, A15, A16	Run `m14.L.h1b`; thresholded lift metrics; call/put panels	A distinct experiment variant with side-specific diagnostics	Meaning of the run suffix, thresholds, units, and split
A8-A11	Run `m14.L.fund3`; Crashed status; `gain.v/lift` curve extending beyond 2G Step; `gain.t`, `gain.v`, `tradability.t` groups	Custom experiment tracking and several metric families	Architecture, metric definitions, smoothing, logging-counter semantics
A12	Model `m14.L.fund3`; `m14_5x200f_553m.pt`; step about 552,710,000; live label; 27 entry days; June/July rows	A named checkpoint associated with one dashboard snapshot	Artifact contents, verified live fills, and meaning of header terms such as pairs
A13	Opening-date grouping and entry-cost formula repeated	Confirms the earlier accounting interpretation	Account-equity return denominator
A14, A17	Expanded August table; total realized PnL $53,917, including $45,855 in August 26 calls	Larger broker and option-side breakdown	Unrealized exposure, total capital, fees, and individual trade outcomes
A18-A21	Complementary views of the earlier table, updated 8/23 at 12:42; August 17-21 dates, broker totals, and call/put split	Dates for the original percentage audit and a comparison of changed cohort values	Why dated Schwab results change between snapshots; underlying trade ledger

The `.pt` filename is consistent with PyTorch conventions, which allow saved tensors, model states, or other serialized objects. It is a strong implementation clue, not proof of a specific network. The apparent checkpoint step is shown wrapped across two lines in A12; reading it together gives approximately 552,710,000. [25]

The `553m` suffix closely matches that counter rounded to millions. Interpreting it as a training/checkpoint identifier is therefore more plausible than interpreting it as a parameter count, although the naming code remains unavailable. `5x200f` could be architecture or feature shorthand; it cannot safely be decoded as five layers of 200 neurons. `L`, `h1b`, and the lift thresholds likewise remain undefined.

The positive and negative percentages in A1 describe volatile cohort outcomes. The clipped Claude reference suggests coding assistance, and the Short PnL sidebar suggests another report; neither identifies the trained model or proves uncovered option selling. The larger, repeated views improve legibility and context without independently authenticating brokerage performance.

3. Reconstructing the displayed PnL

The first screenshot states, in substance: positions are grouped by opening date; realized profit refers to positions already closed; unrealized profit refers to those still open; percentage gain divides their sum by entry cost. The complementary views in A18-A21 now identify the dates and broker columns for the same earlier snapshot, labeled updated 8/23 at 12:42. The date assignments below combine these views. [A1, A18-A21]

Entry date	Realized	Unrealized	Net PnL	Displayed gain	Entry cost implied by that row
2026-08-21	$0	-$2,474	-$2,474	-7.6%	$32,553
2026-08-20	-$3,417	$0	-$3,417	-10.9%	$31,349
2026-08-19	$2,773	$0	$2,773	8.7%	$31,874
2026-08-18	$5,278	$0	$5,278	24.9%	$21,197
2026-08-17	$5,421	$0	$5,421	39.4%	$13,759
Total	$10,055	-$2,474	$7,581	7.7% shown	Approximately $130,730 implied

Calculation: implied entry cost equals net row PnL divided by the displayed row return in decimal form. Summing these inferred costs gives $130,730.49. Dividing $7,581 by that amount gives 5.799%, not 7.7%. Allowing each displayed percentage to have rounded to the nearest 0.1 percentage point produces total implied cost of approximately $130,133-$131,335 and a net return of approximately 5.77%-5.83%. Ordinary percentage rounding does not bridge the difference.

One possible explanation is that the total used realized PnL alone: $10,055 / $130,730 is approximately 7.69%. Another is a different denominator or stale aggregation. These are hypotheses, not findings. The correct request is the exact numerator, denominator, valuation time, and inclusion rules for every total.

The longer screenshot's displayed Alpaca rows sum to $34,932, matching that subtotal. The earlier table's visible rows sum to $11,973. An opening-date cohort for August 21 appears as $0 in the earlier narrow view and -$5,053 later. That is consistent with cohort values updating after positions close or are revalued; it is not itself a reconstructed calendar-day loss. A2 and A5 appear duplicated and should not count as independent confirmation.

Even a fully reconciled cohort table cannot answer the central question without total account equity, overnight marks, cash movements, and position timing. Adding cohort percentages, averaging them without weights, or treating eventual profit as profit earned on the opening date would create misleading daily statistics.

Expanded August table and concentration of profit

The follow-up images expose the previously cropped broker and option-side columns. Dates obscured by the presenter inset are aligned with the earlier dated view using the matching Alpaca amounts and row order. They should be treated as contextual alignment across screenshots. [A2, A5, A14, A17]

Entry date	Alpaca	Schwab	Calls	Puts	Realized
2026-08-28	$0	$0	$0	$0	$0
2026-08-27	$5,552	-$1,856	-$382	$4,078	$3,696
2026-08-26	$24,070	$21,785	$45,855	$0	$45,855
2026-08-25	-$2,777	-$1,303	-$4,130	$50	-$4,080
2026-08-24	$1,167	$3,698	$6,050	-$1,185	$4,865
2026-08-21	-$5,053	-$1,178	-$2,969	-$3,262	-$6,231
2026-08-20	-$683	-$1,673	$451	-$2,807	-$2,356
2026-08-19	$1,874	-$162	-$3,429	$5,142	$1,712
2026-08-18	$6,697	-$2,360	$4,337	$0	$4,337
2026-08-17	$4,085	$2,033	-$5,102	$11,220	$6,118
Displayed total	$34,932	$18,985	$40,681	$13,236	$53,917

The displayed subtotals reconcile exactly: $34,932 + $18,985 = $53,917, and $40,681 + $13,236 = $53,917. Summed visible Schwab rows give $18,984 and realized rows give $53,916, each $1 below the displayed total. This is consistent with rounding or small display differences. It is materially different from the percentage discrepancy in the older view.

Concentration calculation	Result
August 26 cohort share of displayed realized profit	$45,855 / $53,917 = approximately 85.0%
Displayed total excluding that cohort	Approximately $8,062
Other call cohorts combined	$40,681 - $45,855 = -$5,174

This supports a hypothesis that large winners are important to the sample. It does not establish a trade-level payoff distribution, a single winning trade, or profit earned entirely on August 26. Test whether the favorable outcomes recur across independent periods and whether capital survives the intervening losses. The unrealized and percentage fields remain cropped, so $53,917 is displayed realized profit rather than a verified net account return.

The 27-entry-day label belongs to the June/July view in A12, whereas this table shows August. Do not divide the August profit by 27 to estimate average daily profit. Screenshot capture dates also differ from the trading dates shown inside the images.

Same-date broker figures change between snapshots

The four additional images confirm the earlier broker split: Alpaca +$11,973 and Schwab -$1,918, totaling +$10,055 realized. Calls -$3,500 plus puts +$13,555 also total +$10,055. Subtracting the displayed $2,474 unrealized loss gives +$7,581 combined PnL. Thus the earlier snapshot is put-led, whereas the later August sample is call-led. This does not by itself identify a market regime or prove that the model deliberately switched strategies. [A18-A21, A14, A17]

Comparing the same opening dates across the earlier and later views exposes changes in Schwab's reported cohort figures:

Entry date	Earlier Schwab figure	Later Schwab figure	Change
2026-08-20	-$2,734	-$1,673	+$1,061
2026-08-19	+$899	-$162	-$1,061
2026-08-18	-$1,419	-$2,360	-$941
2026-08-17	+$1,336	+$2,033	+$697

The August 20 improvement and August 19 deterioration offset exactly at $1,061. Possible explanations include trade reallocation between opening-date groups, accounting corrections, or later updates; the screenshots cannot establish which explanation applies. Link every cohort value to stable trade IDs and timestamped ledger events to resolve the difference. A changing opening-date figure must not automatically be interpreted as a new day's trading profit.

These four views clarify the earlier sample and strengthen the need for reconciliation. They do not add independent trading days, an account-equity denominator, model weights, or new architecture details. The original 7.7% total versus approximately 5.8% under the stated net-PnL formula remains unresolved.

4. Define the 1% objective correctly

There are several different possible targets: more than 1% on every trading day; an arithmetic daily average above 1%; a geometric daily growth rate above 1%; or more than 1% on deployed option premium. These are different claims. I interpret the demanding version of your goal as growth of total strategy account equity after trading costs, while explicitly allowing losing days.

For an account with no external cash movements, daily return is ending net liquidation equity divided by beginning equity, minus one. With cash flows occurring at the measurement boundary, subtract net external inflows from ending equity before dividing by beginning equity. With intraday deposits or withdrawals, value subperiods and link their returns, or use an appropriate cash-flow-weighted approximation. Do not apply a simple end-of-day adjustment indiscriminately to timed intraday flows.

Net equity includes all cash, positions, stock acquired through exercise, liabilities, financing, and accrued trading costs. Conservative liquidation marks and broker statement marks should both be tracked. Show strategy operating costs separately and also calculate an all-in result including attributable data and infrastructure expense. Taxes depend on the investor and should be shown separately rather than hidden in a generic return claim.

Hypothetical result	Account implication
5% option gain on premium equal to 20% of starting equity, one isolated same-day cohort	Approximately 1% account gain before other costs
5% option gain on premium equal to 5% of equity	Approximately 0.25% account gain
$500 profit on $5,000 premium held for five days	10% cohort return; daily account return still unknown
1% compounded for 21 trading days	23.24% total growth
1% compounded for 252 trading days	12.274 times starting equity; 1,127.4% total gain
5% compounded for 252 trading days	Approximately 218,627 times starting equity

These are mathematical implications, not forecasts. Constant 1% geometric daily growth would turn $100,000 into approximately $1.227 million over 252 trading days before taxes. Scaling, liquidity, costs, and losses make extrapolating short option streaks especially unreliable. The absence of supporting evidence is not a proof that a particular strong day or short interval is impossible.

5. Win rate: secondary, but the payoff distribution matters

You are right to prioritize returns over the fraction of winning trades. A high win rate can conceal rare severe losses, and a low win rate can be profitable when winners sufficiently outweigh losers. But win rate is not irrelevant to the distribution of drawdowns, losing streaks, and capital required to survive.

For equally sized positions measured on the same capital basis, expected trade return is the probability of winning times the average winning return, minus the probability of losing times the average loss magnitude, minus expected costs.

Toy strategy, before costs	Expected premium return per trade
30% chance of +40%; 70% chance of -10%	+5.0%
90% chance of +2%; 10% chance of -30%	-1.2%

Neither is a forecast. The first example's assumed -10% loss is not guaranteed by placing a stop order. An option can gap through a stop or become difficult to sell. If 20% of account equity funded one such position, the stylized outcomes would be +8% or -2% of equity, with an arithmetic expectation of +1%; an unanticipated full premium loss would instead cost 20% of equity. Sizing from the intended stop alone conceals that exposure.

Arithmetic and compounded performance also differ. A +50% day followed by a -50% day has a zero arithmetic average but loses 25% of starting capital. Optimize a constrained growth objective, such as expected log wealth, while controlling tail losses and turnover. Log-growth optimization still depends on uncertain forecasts and cannot manufacture an edge.

Report daily account returns, compounded growth, maximum drawdown, recovery time, expected shortfall, worst losing streak, and profit concentration. Also report the fraction of days exceeding +1%, the fraction of losing days, and win rate as diagnostics. A strategy whose profit comes from one exceptional option should be identified as such. In the expanded screenshot sample, approximately 85% of displayed realized profit comes from one opening-date cohort. Report that dependence separately from individual-trade concentration, which cannot be reconstructed from these images.

6. What published research actually establishes

The most useful evidence supports disciplined experimentation rather than a promised daily return.

Primary study	Relevant finding	Transferable idea	Boundary
Bali, Beckmeyer, Morke, Weigert; Review of Financial Studies, 2023 [2]	Nonlinear models improve out-of-sample option-return prediction using a large historical panel	Combine option and underlying information; compare models and ensembles	A published historical portfolio study is not this owner's live account
Their accessible 2021 working-paper version [3]	Predicts monthly excess delta-hedged returns; compares regularized linear, tree, and feed-forward models	Clear target definition and chronological validation	Monthly hedged results cannot be relabeled daily premium or account returns
Tan, Roberts, Zohren; 2024 preprint [4]	Studies direct signal learning on equity-option portfolios and turnover-aware training	Compare simple and sequence models; include costs in optimization	Uses end-of-day data and approximately one-month straddles, rather than a demonstrated intraday account system
Buehler, Gonon, Teichmann, Wood; Deep Hedging [5]	Learns derivative hedges with frictions and risk constraints	Train decisions against economic losses and constraints	Better hedging is not proof of profitable directional alpha
Bailey and coauthors; backtest overfitting and Deflated Sharpe Ratio [7, 8]	Strategy selection and repeated trials inflate apparent performance	Record all trials and adjust performance assessment	A single attractive holdout or chart does not remove selection bias

The accessible 2021 and final 2023 versions of the Bali paper have different transaction-cost analyses. Do not combine numerical results from different versions. The relevant lesson here is that horizon, hedge accounting, costs, and return denominator must travel with every reported statistic; a portfolio spread is not automatically a fully funded retail account return.

A recent working-paper abstract by Dorion, Orlowski, and Song reports that a factor-neutral 0DTE strategy becomes infeasible under minimal transaction costs. This is an authors' preprint claim reviewed here at abstract level, not a universal finding that every 0DTE strategy fails. It reinforces the need to test execution costs rather than assume them away. [24]

I found no publicly retrievable specification, model weights, source repository, or independently verified track record for the exact `m14.fund3` system in the screenshots. Exact-name searches and attempts to retrieve the displayed dashboard and apparent experiment project did not expose a reproducible strategy.

7. Reconstructing the model and deployment workflow

The visible modules support the following engineering reconstruction. The exact proprietary implementation remains unavailable.

1. A scanner builds an eligible market universe.
2. A feature pipeline produces model inputs.
3. Training creates versioned checkpoints and logs gain-related metrics.
4. Selection and ranking turn predictions into candidate trades.
5. Tradability or eligibility filters and portfolio controls constrain entries.
6. Broker-specific workers route orders and manage positions.
7. An independent exit scheduler and reconciliation jobs maintain state.
8. Dashboards expose health, positions, opening-date outcomes, and checkpoint metadata.

The model checkpoint in A12 strengthens the connection between training artifacts and the trading dashboard. It does not expose the artifact or prove that every displayed PnL table used the same weights. The deployment name `m14.fund3` and training name `m14.L.fund3` should be linked through an explicit model registry rather than assumed identical from their spelling.

What the counters and metrics do, and do not, establish

The fund3 chart reaches a Step value of 2,119,092,800, while the checkpoint panel names about 552,710,000. These could be different snapshots or counter conventions. The evidence does not establish that the latest plotted weights generated the displayed trades. Preserve the exact checkpoint hash, code version, data cutoff, and activation time for every decision.

The `gain.t`, `gain.v`, and `tradability.t` groups plausibly distinguish training, validation, and execution-related measurements. That is a naming inference. The letter v does not prove an untouched validation set or chronological evaluation. Separate call and put diagnostics are visible, but separate neural output heads are not.

The tooltips show `8.50069 (-1.66798)` at one location and `9.73016 (13.33021)` at another. Their paired-value convention is not defined. W&B permits smoothing and configurable axes; those capabilities make plot settings relevant, but do not establish which transformation produced this graph. Obtain the original logged values and the `gain.v/lift` function before interpreting a value as a percentage, ratio, or monetary result. [27]

The curve generally rises during the experiment, with substantial reversals. This establishes an improvement in the displayed custom metric over parts of the logged counter. It does not establish daily account growth, an independent equity curve, or 9.73% daily returns. Threshold names such as `2+` and `4+` require their original definitions.

Experiment state and claimed live status

One fund3 run is marked Crashed, while h1b is shown Running. W&B's official SDK describes Crashed as a stopped heartbeat from the run's internal process. That status alone does not diagnose financial losses or a brokerage failure. A model-serving process and a training/logging process can have different operational states. [26]

The June/July dashboard is explicitly labeled live. This revises the first edition's uncertainty about whether any visible view claimed live operation. It is evidence of the application's categorization; authentication requires broker fills, activities, and account statements. The header's pairs terminology and its account/count meaning remain ambiguous. Open legs and open contracts do not, by themselves, identify straddles, pairs trading, or the number of underlying stocks.

The `kooshiar-na` workspace is a lead toward original source material, not independent identity or performance verification. The public pages previously reviewed list option pricing and quantitative finance interests but do not supply the missing model specification. The exact h1b run URL newly visible in A15/A16 was also attempted and could not be retrieved through the research service. [1]

For a reproduction, preserve the separation of training, checkpoint activation, model inference, risk, execution, exits, and accounting. The best-supported next technical request is the Overview/Config panel, feature and target definitions, metric code, and the mapping from checkpoint versions to actual orders.

8. Candidate strategies and a sensible research order

Daily measurement does not require options that expire daily. A system can measure account returns every day while holding options with several weeks until expiration. The appropriate contract depends on the forecast horizon, volatility exposure, liquidity, and risk budget.

Candidate	Proposed prediction target	Instruments to investigate	Research priority
Directional selection	Net executable return distribution over a fixed horizon	Long calls/puts; separately tested debit spreads	First: closest to the visible call/put allocation idea
Cross-sectional ranking	Relative future option return after controlling for common exposures	A limited set of liquid stock or ETF options	Second: closest to the published prediction literature
Volatility selection	Realized movement and future IV relative to option cost	Long straddles or defined-risk spreads	Separate sleeve: requires different labels and risk accounting
Exit optimization	Incremental value of holding versus closing	Existing positions only	After a fixed exit rule provides a benchmark
0DTE trading	Very short-horizon option PnL with detailed execution	Only contracts and broker facilities explicitly supported	Later: sensitive to quote timing, gamma, and liquidation constraints

Candidate	Proposed prediction target	Instruments to investigate	Research priority
Uncovered short volatility	Return net of jump exposure and collateral cost	Naked option sales	Exclude from the initial design; small premiums can obscure large obligations

FINRA describes rapid-loss and broker-liquidation risks in expiring options. These are essential simulation cases for any 0DTE experiment. [23]

For a first experiment, use SPY and QQQ option chains rather than a broad changing stock universe. This is an engineering simplification and a hypothesis to test, not a claim of superior returns. SPY and QQQ exposures are correlated and should share a portfolio risk bucket. Expand to individual stocks only after corporate actions, earnings timing, and sector concentration are handled correctly.

Predeclare a small candidate grid of expiry bands, absolute deltas, and holding horizons. For example, test 5-10, 11-21, and 22-45 calendar DTE with moderate absolute deltas and an intraday-to-next-day horizon. These are experiment settings, not optimized trading recommendations. Count every combination as a research trial and use the same data and cost assumptions across models.

SPX-style index contracts require separate settlement handling and verified broker support. Cboe distinguishes cash-settled European SPX/XSP contracts from physically settled American SPY options, including different AM/PM settlement conventions. Do not route all contracts through a generic expiry rule. [18]

9. Proposed end-to-end architecture

Use a reproducible research pipeline feeding a controlled execution service. The risk controller must be able to reject a model's proposal; no language model should be able to override its limits.

Component	Main responsibility	Stored evidence
Raw data store	Preserve original quotes, trades, reference data, and release times	Immutable files, checksums, vendor/schema versions
Contract master	Track exact contract identity, multiplier, deliverable, style, and expiry	Effective-dated instrument definitions
Feature builder	Construct only information available by each decision time	As-of joins, feature version, availability checks
Label builder	Construct executable outcomes over predeclared horizons	Entry/exit times, quotes, fees, expiry treatment
Model registry	Compare baselines and challengers	Frozen model, training window, parameters, trial history
Portfolio controller	Convert edge estimates into allowed positions	Risk budgets, Greeks, correlation buckets, rejection reasons

Component	Main responsibility	Stored evidence
Order service	Submit, track, cancel, and reconcile orders	Client order IDs, acknowledgments, fills, latency
Exit service	Manage exits independently of entry scanning	Due times, actual close state, overdue alerts
Ledger	Reconcile economic positions and account equity	Cash events, trades, exercises, assignments, fees
Monitoring	Detect stale data, drift, outages, and accounting breaks	Alerts, health timestamps, operator actions

An ordinary CPU is sufficient to start with filtered data and tree models. Use columnar historical files for research and a transactional store for live state. A single reproducible batch job and one execution worker are preferable to unnecessary distributed complexity during validation. This is a proposed implementation choice, not an inference about the screenshots' backend.

Maintain a checkpoint-to-order audit trail: checkpoint filename and hash, training and data cutoffs, activation time, feature version, and exact trade decisions. A research run progressing beyond a deployed checkpoint must not silently change the model credited with earlier results.

The dashboard should have separate calendar-day account performance and opening-date cohort performance views. Label the denominator, valuation method, fee treatment, and holding-period basis directly beside each percentage. Preserve the useful operational screens shown in the attachments, but add a mandatory equity and cash-flow reconciliation panel.

10. Data: buy the information the experiment needs

Free underlying price bars are insufficient to validate an intraday option strategy. The experiment needs historical option quotes, exact expired contracts, contract changes, underlying prices, and data availability timing. A current option chain cannot reconstruct a historical chain without survivorship bias.

Source, verified from official documentation	Useful capability	Important boundary
Cboe DataShop Option Quotes [9]	Historical interval NBBO data from January 2012; optional IV and Greeks	Snapshots do not establish intraminute fills or event order
Massive options flat files [10]	OPRA-derived quotes, trades, and aggregates	Confirm plan entitlements, coverage, size, and live feed separately
Databento OPRA [11, 12]	Consolidated options data and instrument definitions; historical catalog extends to April 2013	Pre-March 28, 2023 data have different granularity and timestamp limitations
OptionMetrics IvyDB US [14]	End-of-day options and related analytics from January 1996	Appropriate for daily research; end-of-day data alone cannot validate intraday execution

Source, verified from official documentation	Useful capability	Important boundary
Alpaca historical options [13]	Historical API data from February 2024	Shorter regime history; its indicative feed is not actual OPRA quotes

Two current documentation details materially affect backtesting. Cboe changed its interval quote-size capture convention effective June 22, 2026. Databento says earlier-than-March-28-2023 OPRA data were subsampled, have different schema availability, and do not provide equivalent capture-received timestamps. Test these periods separately before attributing differences to market regimes. [9, 11]

Run a vendor sample comparison on the same small set of contracts and dates before buying broad history. Include a normal day, a volatile day, an early close, an expiry, and a corporate action if using stocks. Check bid/ask consistency, timestamps, absent contracts, missing intervals, quote sizes, and whether the underlying price is synchronized.

Do not download the entire options market by default. Data volume can dominate the project. Obtain an explicit quote for the intended universe, resolution, history, index licensing, and non-display use. Provider plan prices alone do not establish the total cost of a reproducible research and execution setup.

11. Features and labels that avoid future information

Direction alone is not the target. An option can lose value while its underlying moves the predicted way because the move is too small or late, implied volatility falls, or trading costs exceed the gain. Implied volatility is a pricing input and is not automatically a physical probability forecast.

Feature family	Candidate inputs	Main timing hazard
Contract and surface	DTE, moneyness, delta, gamma, theta, vega, skew, term structure	Using end-of-day or future-smoothed analytics at an intraday decision
Liquidity	Bid/ask width, available size, quote age, recent volume	Assuming quoted size guarantees a fill or reading future interval volume
Underlying	Returns, realized volatility, range, trend, reversal, volume	Mixing adjusted historical stock prices with unadjusted option strikes
Market and regime	Index movement, volatility state, sector exposure	Using revised or late-published values before release
Calendar and events	Time of day, expiry proximity, earnings schedule, known macro events	Using the realized event outcome or a retrospectively corrected timestamp
Portfolio state	Existing Greeks, committed premium, concentration	Training on a state definition different from execution

Store event time, known-available time, ingestion time where available, and decision time. Features require availability at or before decision time. Historical events need not include the user's actual ingestion timestamp, but the replay must impose a conservative availability and latency rule rather than invent historical knowledge.

For a long option with multiplier m, define a unit-contract dollar label as m times the executable exit bid minus executable entry ask, less both sides' fees and modeled slippage. Convert to premium return using actual entry outlay. A neutral target should retain the dollar label as well, because tiny premiums can create extreme and misleading percentage rankings.

For a two-leg spread, compute the combined executable debit or credit and account for both legs, fills, and fees. A complex-order midpoint is not a guaranteed fill. Incorporate exercise, assignment, contract adjustments, and expiry where the horizon permits them. For a directional strategy, use directional labels; for a delta-hedged strategy, include the stock hedge and its cost in both labels and results.

Keep a label for each predeclared horizon and train quantiles or other distribution estimates alongside the expected return. A model trained on the best future exit price is learning an unavailable oracle unless a feasible exit policy is separately specified and tested.

12. Which AI models to train, and in what order

Different models should compete on the same economic decision, data windows, trading constraints, and cost assumptions. More architectures increase the chance of selecting noise unless the entire search history is retained.

Model family	Proposed job	Initial role	Advancement condition
Regularized linear regression or calibrated classifier	Predict net outcomes or probability of clearing costs	Mandatory baseline	Establish whether complex interactions add value
Gradient-boosted trees, such as LightGBM	Learn nonlinear relationships in contract, surface, and market features	Primary initial model	Stable net performance beyond the linear and rule baselines
Small feed-forward neural network	Predict economic option outcomes	Initial neural candidate alongside trees	Independent improvement across chronological windows and seeds
Causal CNN/TCN or LSTM	Use a fixed history of market and surface state	Sequence challenger	Incremental value beyond trees using comparable lag features
Temporal Fusion Transformer or a small causal transformer	Multi-horizon conditional forecasts	Optional later experiment	Enough data and evidence to justify complexity; architecture alone is not an edge [6]
Distribution or quantile models	Estimate downside, uncertainty, and gain distribution	Risk and abstention support	Adequate out-of-sample calibration
Reinforcement learning	Constrained exits, execution, or hedging	Later-stage experiment	Beats a fixed policy in a realistic simulator and forward evaluation [5]

Model family	Proposed job	Initial role	Advancement condition
Language model	Extract structured event information or support research	Optional auxiliary input	Point-in-time provenance and measurable incremental value

The checkpoint evidence warrants a supervised neural model in the initial comparison alongside boosted trees and mandatory simple baselines. Compare a gain-only network with a network that also predicts tradability, separate call/put outcomes, and downside or uncertainty. These are proposed ablations; the metric names do not prove the owner implemented those heads. Define tradability labels and their future outcome windows explicitly, keeping all predictive inputs available at decision time.

Train each family with limited, predeclared search budgets, early stopping on validation data, and reproducible seeds. Standardization, winsorization, category maps, and imputation must be fitted only on training data. Treat missingness consistently rather than dropping future-problematic observations after seeing outcomes.

Ensemble only when the members contribute distinct out-of-sample forecast information or residual risk. Begin with a fixed blend or median forecast. Learn ensemble weights inside the training/validation process, not on the final test period. Ten correlated models are not ten independent sources of protection.

Do not begin by training a large language model to output buy and sell instructions. Financial text may contain future information relative to the historical trade date, and an otherwise helpful language model still lacks demonstrated executable edge. Restrict its authority to bounded, logged tasks and evaluate those tasks separately.

A concrete first experiment contract

To make this actionable, pre-register a deliberately narrow experiment before examining its final test period. One candidate specification is SPY and QQQ, standard unadjusted long calls and puts, 7-21 calendar DTE, absolute delta 0.35-0.60, decisions every 15 minutes after a completed feature interval, and a fixed 60-minute holding policy. Reject entries that cannot complete before a predeclared session cutoff. Use only complete historical sessions available at the research cutoff, not future or partially observed sessions. These settings are a proposed starting experiment, not settings known to be profitable.

Train on unit-contract net dollar PnL and a corresponding premium-return label; retain both so ranking cannot be dominated by tiny premiums. Use executable post-decision quotes and an explicit latency rule. Initially permit at most one open position per underlying, keep both ETFs in the same correlation bucket, and account for integer contract sizes. Select the eligible contract with the best estimated incremental net contribution only if the abstention rule and risk constraints permit it. Freeze a simple exit policy before comparing learned exits.

Compare a fixed momentum rule, elastic net, boosted trees, a small two-layer neural network, and one LSTM or causal convolution challenger. Cap each model's tuning budget in advance and record every attempted configuration and seed. For tree models, vary depth/leaves, minimum leaf observations, learning rate, and regularization; for neural models, vary width, dropout, weight decay, and sequence length. Do not expand the search because the holdout disappoints.

Primary promotion criteria are net calendar-day account performance, drawdown, uncertainty, and stability against executable-cost stress. Prediction error and win rate are secondary diagnostics. Only after this

contract survives should the experiment expand its universe, tenors, structures, exit flexibility, or live authority.

13. Training and validation protocol

Use chronological, nested evaluation. Randomly splitting option rows lets related contracts, repeated observations, and overlapping outcomes leak information across train and test sets. Thousands of options observed on the same day do not constitute thousands of independent market histories.

An illustrative sequence is to train on 2018-2021, validate on 2022, and test on 2023, then roll the process forward through subsequent years. At each step, learn preprocessing, tune parameters, and choose models only with data that would then have been available. This is a proposed protocol, not an executed result. Reserve the latest suitable contiguous period for one final assessment only if it has genuinely remained untouched during strategy design.

Check	Required implementation
Overlapping labels	Purge training examples whose outcome windows cross a validation or test boundary
Temporal separation	Insert an appropriate gap; use embargo where the chosen cross-validation design needs it
Shared market dates	Keep contemporaneous observations together in temporal evaluation; use date-aware uncertainty estimates
Contract lifecycle	Include expired and delisted instruments; handle adjusted contracts explicitly
Data revisions	Retain or simulate the information version available at the decision date
Hyperparameter selection	Tune within training/validation windows, then freeze the next test window
Strategy search	Record unsuccessful trials, alternative filters, exits, and universe choices
External holdout	Do not repeatedly inspect and retune against it

For uncertainty, resample blocks of calendar-day account returns with all positions kept together, rather than resampling correlated trades independently. Explore sensitivity to block length and regime. Sharpe confidence estimates need attention to serial correlation and non-normality. Use the Deflated Sharpe Ratio and probability-of-overfitting methods as additional diagnostics where their assumptions and available trial records permit them. [7, 8]

Run ablations: remove option-surface features, underlying features, sequence history, and ensemble members in turn. Compare a no-trade baseline, a simple fixed rule, a linear model, and equal-rule option portfolios under identical execution assumptions. Shift labels or randomize them inside a deliberately controlled diagnostic; a persistent apparent edge is a reason to inspect leakage and search effects, not to celebrate.

Report every chronological window, including failure periods. Aggregating only the best model from each period after observing the period would create a strategy that could not have existed in real time.

14. Execution simulation: where a paper edge often disappears

Build an event-driven simulator around what could have been submitted and filled. For a deliberately conservative long-option baseline, buy at a valid post-decision ask and sell at a valid post-exit-decision bid, with additional latency, capacity limits, and actual fees. That is a baseline assumption, not a guarantee of those fills. Market movement between decision, submission, and exchange acknowledgment can make execution worse.

Limit orders can improve price but can also remain unfilled. A midpoint appearing on a quote screen does not imply your order would execute there. Official options education describes the price-versus-fill tradeoff and the importance of available bid/ask liquidity. [22]

Illustrative arithmetic: an option is quoted $1.95/$2.05, midpoint $2.00. Later it is $2.05/$2.15, midpoint $2.10. A midpoint-only backtest records a 5% gain. Buying at the initial ask and selling at the later bid produces zero gross gain; fees turn it into a loss. With an unchanged $1.95/$2.05 quote, immediately crossing both sides loses $10 per standard contract before fees, or about 4.88% of the $205 purchase cost.

Required handling includes quote staleness and crossed markets; order size relative to accessible liquidity; partial fills; cancel/replace races; rejected orders; outages; transaction fees; early closes; and the ordering of events within bars. If a bar hits both a stop and a profit target, its high and low alone cannot tell which happened first. Use finer data or a conservative unresolved-case rule.

For spreads, simulate a supported complex order or conservative leg handling. Do not independently assume every leg fills at an advantageous midpoint. Reject a strategy if most of its profit depends on unverifiable favorable fill assumptions.

Alpaca explicitly says its paper environment omits factors including market impact, latency slippage, queue position, and regulatory fees. Therefore, an Alpaca-labeled PnL column cannot by itself establish live achievable performance. Paper mode is valuable for workflow and reconciliation checks; a later controlled live pilot is needed to measure actual fills if the strategy first passes research review. [16]

15. Portfolio sizing and the target's risk implications

Keep forecast generation separate from position sizing. Rank candidates by expected net dollar contribution, downside, and incremental portfolio exposure, rather than the largest predicted percentage on the cheapest option. Size only after accounting for already-open and pending orders.

For long options, full premium plus costs is the relevant contractual loss before any exercise-related stock exposure. For debit spreads, use the properly constructed defined-risk loss and account for assignment, exercise, and legging complications. An intended stop does not turn an option into a guaranteed smaller-loss instrument. OCC explains the possibility of losing the entire premium and the obligations associated with exercise and assignment. [19, 20]

The following is an illustrative conservative pilot configuration to make the engineering test concrete. It is not calibrated to your finances and is not a guarantee of bounded realized daily loss.

Control	Example research setting	Interpretation
Maximum contractual loss for a new position	0.25%-0.50% of equity	Based on full premium/defined loss, not the intended stop
Total simultaneous option premium or defined-risk loss	At most 5% of equity	Also include pending orders and correlated scenarios
Same underlying or strongly correlated bucket	At most 2% of equity	Treat overlapping ETF and technology exposure together
Daily loss trigger	Around 1%-1.5% of beginning equity	Stop new entries and initiate risk reduction; execution can overshoot
Pilot drawdown review trigger	Around 5% from the high-water mark	Pause and investigate rather than increase leverage
Overnight exposure	Disabled initially	Add only after separate gap-risk testing

These controls may leave the system unable to approach a 1% average daily goal. With only 5% of equity deployed in one same-day cohort, a 1% account gain requires a 20% gain on that premium before further costs. More turnover does not automatically help, because it creates repeated spreads, fees, correlation, and loss opportunities.

Stress net delta, gamma, vega, theta, volatility crush, market gaps, and correlated positions. Use realistic joint scenarios rather than assuming unrelated option trades diversify one another. Do not increase position sizes to recover losses or force a daily profit target. The actual risk budget must be chosen from your capital, liquidity needs, and acceptable drawdown before any deployment.

16. Broker integration and operational controls

The screenshot's dual-broker design is operationally plausible: Alpaca publishes options trading APIs, while Schwab's individual Trader API supports account access, market data, and trading. Public availability does not imply that a particular account is approved for every strategy or product. [15, 17]

Start with one broker so fills, fees, and account states can be reconciled unambiguously. Add a second only when there is a measured operational or execution benefit. Validate product support, option approval level, complex orders, order types, rate limits, authentication refresh, expirations, and exercise procedures using that broker's current documentation and account settings.

Failure mode	Required behavior
Stale or missing market data	Reject new entries; evaluate existing exposure through the risk service
Unknown order outcome after timeout	Query and reconcile by stable client order ID before resubmitting

Failure mode	Required behavior
Duplicate scheduler invocation	Idempotent position and order transitions
Partial close	Retain residual exposure and continue monitored handling
Authentication failure	Alert, block new orders, and activate documented manual intervention
Position mismatch	Block new risk until ledger and broker state agree
Approaching expiry or overdue exit	Escalate independently of the entry model
Model or feature version mismatch	Reject the signal and record why

Alpaca's documentation describes exercise and assignment events and says assignments are not delivered through its websocket events, so polling and next-day reconciliation cannot be omitted. Its paper non-trade activity timing also differs from immediate balance changes. [15]

As of October 29, 2026, blanket statements that every U.S. day trader must maintain $25,000 are incomplete. FINRA's replacement intraday-margin standards became effective June 4, 2026, with a permitted firm transition through October 20, 2027. A broker may still use the earlier regime during transition; confirm the regime and house rules for the actual account. Cash-account settlement constraints also require explicit handling. [21]

17. How to measure success honestly

The main report card must begin with account-level calendar-day returns after executable trading costs. Keep cohort returns as a useful explanation of which entries contributed profit, with a different label and denominator.

Measurement	Why it matters
Beginning and ending account equity with timed cash flows	Establishes the actual capital base
Gross and net PnL, with spread/slippage/fees separated	Shows whether the modeled signal survives implementation
Arithmetic average daily return and geometric growth	Separates expected daily PnL from compounding
Fraction of days above +1%; losing days; worst day	Directly evaluates the stated target's distribution
Maximum drawdown, recovery time, expected shortfall	Measures the cost of surviving the strategy
Exposure-adjusted benchmarks	Distinguishes model contribution from leveraged market or volatility exposure

Measurement	Why it matters
Rolling and regime results	Detects dependence on one market period
Top-day and top-trade profit concentration	Reveals rare-event dependence
Capacity, fill rate, execution shortfall, latency	Tests whether the result can be traded at intended size
All-in operating cost at actual account size	Prevents a small gross edge from hiding an economic loss

Predeclare what would count as support for each claim. A positive estimate of average return is not evidence that the true average exceeds 1%. A confidence interval entirely above zero supports a different statement from one entirely above +1%. Both are vulnerable to nonstationarity and research selection, even with careful statistical treatment.

For example, an estimated daily mean of +1.2% whose interval includes -0.3% and +2.7% does not establish either positive expected performance or a 1% threshold. This interval is hypothetical, provided solely to illustrate the interpretation.

Sixty trading days can help test operations but cannot establish durability across market regimes. A large trade count cannot substitute for independent time and differing conditions. Match model promotion to both economic magnitude and uncertainty, and publish failed windows rather than reporting only the best aggregate number.

18. A staged implementation plan

The time ranges below are planning estimates for a focused builder with appropriate data access; they are not delivery commitments or evidence of future profitability. Historical data preparation can dominate the schedule.

Stage	Work	Reviewable output	Advance only when
1: definition and audit	Specify return denominator, universe, horizon, risk, and source evidence	Written experiment contract; screenshot ledger questions	Accounting and success criteria are unambiguous
2: data sample	Compare small matched vendor samples; build contract master	Data quality and timing report	Historical contracts and executable quotes can be reconstructed
3: baseline research	Build labels and simulator; train fixed rules, linear, and trees	Full chronological results with cost sensitivity	Net edge survives realistic assumptions
4: challengers	Add small neural and sequence models; constrained ensemble	Trial registry, ablations, calibrated predictions	Incremental value survives new windows and search adjustment
5: operational shadow mode	Run signals and paper orders; deliberately test failures	Reconciled ledger and exception log	No unexplained position/cash mismatches or duplicate orders

Stage	Work	Reviewable output	Advance only when
6: controlled live pilot	Only after separate authorization and review, use small defined risk	Real fill and slippage evidence	Real economics and operational behavior support continuation
7: gradual scale	Increase size in measured steps	Capacity and risk review at each step	Edge persists and risk remains within the chosen budget

A focused research prototype could take roughly 6-12 weeks if data and engineering resources are available. A short prototype is not a validated investment system. Shadow evaluation and any live evidence require additional calendar time; multi-regime evidence usually requires substantially more history and ongoing monitoring.

The first deliverable should be a reproducible research package: data dictionary, code revision, frozen splits, label specification, complete trial log, executable simulator assumptions, account return calculation, and an exception report. A visually persuasive dashboard is useful after these foundations exist.

Do not solve a failure to reach 1% by changing the denominator, excluding losing positions, increasing leverage, or reusing the final holdout. A strategy can pass a positive-edge test and fail the high-return target. That is a meaningful research result and should remain visible.

19. Costs, priorities, and the information still needed

Separate research budget from trading capital. A credible total depends on the universe, data depth, number of dates, quote resolution, licensing status, storage, and whether live execution is attempted. Current vendor documentation confirms that coverage and entitlement differ materially; a single subscription price is not a complete project quote. [9-14]

Budget category	What to specify before spending
Historical data	Symbols, expired chains, date range, quote/trade resolution, analytics, corrections
Live data	Actual OPRA entitlement, underlying feed, index licensing where relevant
Compute and storage	Filtered dataset size, replay frequency, archival and backup needs
Brokerage	Per-contract fees, exchange/regulatory charges, order support, financing
Engineering	Data cleaning, research reproducibility, order lifecycle, monitoring, reconciliation
Trading capital	Risk budget, discrete contract size, margin/cash rules, adverse scenarios

Start with a narrowly scoped sample and CPU-based baselines. Do not buy a large GPU because the experiment screenshot shows a long training run. Better execution data, a correct ledger, and strict validation are higher priorities than parameter count for this project.

The current unknowns that would materially change a deployment design are: starting account size; jurisdiction and broker eligibility; maximum acceptable drawdown and daily loss; intraday-only versus overnight holding; acceptable option structures; historical data budget; engineering resources; and access to the original presentation, code, or ledger. This research assumes U.S. products because those are visible in the screenshots. It does not assume your location or account approval.

The most valuable next evidence is the original full video or explanation plus a complete broker-reconciled equity history. That can clarify whether the method's claimed return is on premium, margin, deployed capital, or all account equity, and whether its entry cohorts span multiple days. The screenshots alone cannot recover those missing definitions.

20. Exact evidence required to assess the 5% claim

Request a contiguous record rather than selected screenshots. At minimum, collect:

1. Daily and, if available, intraday net liquidation equity from inception, including all losing and inactive days.
2. Timed deposits, withdrawals, transfers, and any changes to capital allocation.
3. Broker export of every order, acknowledgment, fill, cancellation, rejection, and fee, with paper/live status.
4. Every position's contract ID, direction, strike, expiry, multiplier, deliverable, quantity, and timestamps.
5. Open-position marks and the exact source and timestamp of those marks.
6. Exercise, assignment, expiry, corporate-action, financing, and cash adjustments.
7. The exact SQL or code for every PnL percentage, total, and cohort inclusion rule, plus timestamped trade-level explanations for the changes in Schwab figures for the same opening dates.
8. A data manifest, feature definitions, labels, training windows, model revisions, and trial history.
9. Definitions of `gain.v/lift`, its paired tooltip values, all thresholds, `gain.t`, `gain.v`, `tradability.t`, the Step counter, and the meaning of `5x200f`.
10. Checkpoint artifact, hash, architecture/configuration, training cutoff, deployment activation time, and the mapping between `m14.L.fund3` and `m14.fund3`.
11. Complete performance by model and account, including discontinued versions and unsuccessful periods.

Recompute account returns independently, reconcile them to statements, then compare the result with the dashboard. Check whether both broker columns contain distinct trades or duplicated exposure. Identify whether profits depend on stale or midpoint marks, losing open positions being omitted, or earlier cohorts being retroactively credited to their entry dates. These are audit questions, not accusations.

Strong evidence would consist of a reproducible specification and a long, complete, independently reconciled record after costs. It could demonstrate historical performance without guaranteeing future results. Weak evidence would consist of a short favorable sample, undefined lift metrics, or premium-based gains presented as account returns.

21. Reference decision policy and audit record

This pseudocode specifies a proposed research policy; it is not a runnable or profitable trading bot.

```
At each scheduled decision time:
    reconcile broker cash, positions, fills, and pending orders
    if account state or market data is unreliable: reject new risk
    build eligible contracts using information available now
    construct versioned features and verify availability times
    predict net payoff distribution for each allowed contract/structure
    reject stale, illiquid, uncertain, or negative-edge candidates
    evaluate incremental portfolio risk including pending orders
    select only positions permitted by the fixed risk budget
    submit through an idempotent order service
    record predictions, rejections, orders, and fills

Continuously and independently:
    monitor exits, expiration, fills, residual positions, and risk
    reconcile actual fills before retrying unknown orders
    halt new entries when health or loss triggers activate

At the accounting boundary:
    reconcile cash events and mark every remaining exposure
    compute cash-flow-adjusted account return
    separately update opening-date cohort returns
    store model, data, execution, and accounting versions
```

Each candidate decision should retain: decision ID; model/version; raw-data and feature versions; feature availability time; exact contract identity; forecast mean and quantiles; predicted costs; proposed quantity; portfolio exposures before and after; acceptance/rejection reason; client and broker order IDs; submissions, acknowledgments, fills and cancels; actual cost; exit reason; and final ledger links.

This record separates forecast, sizing, execution, and operational errors, and preserves what was actually known and decided. It makes subsequent learning auditable. The investment decision remains empirical: does net account growth justify the strategy's losses and capacity limits?

22. Source register and verification limits

Primary research and official documentation were prioritized. Web sources were checked on October 29, 2026. Product capabilities, data entitlements, rules, and fees can change. The report uses findings as research context, not as independently replicated performance. Original calculations were performed directly from transcribed screenshot values and elementary return arithmetic.

Boundaries of this research

The displayed txrdash site, apparent Weights & Biases project, and newly visible exact h1b run URL could not be retrieved through the research service, and exact-name searches did not expose their underlying code. All 21 supplied images were visually reviewed; the newly visible run address is https://wandb.ai/kooshiar-na/m10/runs/r7m6m7w9 and is recorded as an unavailable lead, not an inspected source. The application labels one June/July view live, but broker verification remains unavailable. This report does not infer private information from access failures. The owner's precise architecture and live results remain unverified. Historical data vendors were assessed from current official documentation, not from a purchased sample or completeness audit. Source 24 was accessible through its indexed abstract; the full paper was not retrieved. No backtest, historical fill reconstruction, proprietary model replication, brokerage reconciliation, or live order was performed.

The recommended path is to reproduce the visible separation of research, selection, risk, execution, exits, and accounting; correct the return measurement; and test the proposed edge before committing trading capital. The decisive evidence is net account performance under reproducible assumptions and acceptable losses, not the apparent sophistication of the model or dashboard.
